Abstract

We analyze a simple greedy algorithm for finding small dominating sets in undirected graphs of N nodes and M edges. We show that $d_g \leq N + 1 - \sqrt{2M + 1}$, where d_g is the cardinality of the dominating set returned by the algorithm.

Keywords: approximate algorithms, analysis of algorithms.

Introduction

Let $G(V, E)$ be an undirected graph with N nodes and M edges. A dominating set of G is a set of nodes such that every node not in the set is adjacent to at least one node in the set. A dominating set of smallest cardinality is known as a minimum dominating set. The problem of finding a minimum dominating set is combinatorially hard (its decision version is NP-complete [2]), so as a practical matter, one has to settle for approximate, but fast algorithms. In this note, we analyze the performance of a simple, greedy algorithm of this type. Let d_g be the size of the dominating set returned by the greedy algorithm, and let d_o be the cardinality of a minimum dominating set. We show that an upper bound on d_o due to Vizing [5], applies to d_g as well:

$$d_g \leq N + 1 - \sqrt{2M + 1}.$$

Previous Work

The greedy algorithm considered here is an analog of one that has been analyzed by Chvatal [1] and others [3], [4] for finding small set covers. The focus there has been on comparing the cardinality of the set cover returned by the algorithm to that of the smallest set cover, in the worst case. Since any dominating set problem can be formulated as a set covering problem, the results for the set covering algorithm can be

PAGE

specialized to our problem. A result almost directly obtained from the work of Chvatal [1] is that

$$\frac{d_g}{d_o} \leq \sum_{i=1}^{\delta+1} \frac{1}{i},$$

where δ is the maximum degree of a node in the graph. The result of this paper describes the performance of the algorithm in terms of the dimensions of the graph, and should be viewed as complementary to the above result.

Greedy: The Approximation Algorithm

Let $V = \{1, ..., N\}$, and define $D = \phi$. *Greedy* adds a new node to D in each iteration, until D forms a dominating set. A node, j, is said to be "covered" if $j \in D$ or if any neighbor of j is in D. A node that is not covered is said to be uncovered. (Since $D = \phi$ at the beginning of the algorithm, it follows that all the nodes are initially uncovered.) In each iteration, put into D the least indexed node that covers the maximum number of uncovered nodes. Stop when all the nodes are covered. (Selecting the least numbered element is just a way of breaking ties.) An example of *Greedy* at work is provided in Figure 1.

Worst Case Performance in terms of N and M

Here we show that an upper bound on d_o due to Vizing [5] is met by d_g as well:

Theorem 1. *For an undirected graph, G, with N nodes and M edges:*

$$d_g \leq N + 1 - \sqrt{2M + 1}. \tag{1}$$

Proof: First convert G into a directed graph by replacing every edge $\{i, j\}$ by 2 directed edges (i,j) and (j,i), and by adding self-loops (i,i) at every node i. Define the outdegree of a node as the number of edges emanating from it. Any node j, such that (n, j) is an edge in the directed graph, is said to be in the out-neighborhood of n. We can interpret *Greedy* on the constructed directed graph as follows: Include the least indexed node, n, with the greatest outdegree in the dominating set; delete all edges coming into any node in the out-neighborhood of n; and if there are any edges left, include another node in the dominating set, else stop. To see that this is identical to *Greedy*, interpret a directed edge (i,j) to mean that if i were included in the dominating set, the previously uncovered node, j, would be covered by i (see figure 2).

Suppose *Greedy* picks node v_i in the ith iteration. Let $S(i)$ be the set of previously uncovered nodes which were covered by v_i, and let $|S(i)| = m_i$. Finally, define E_i to be

the number of edges left at the end of the ith iteration *coming from uncovered nodes*, i.e., E_i does not include edges from covered nodes. Set $E_0 = 2M + N$, and also notice that $E_{d_g} = 0$. (Observe that when there are no edges left, we have found a dominating set.) Our strategy in the proof is the following: We first find a lower bound on E_0 in terms of the m_i's. Next, we show that this lower bound is no greater than a particular expression that is independent of the m_i's. Algebraic simplification completes the proof.

First we show that at most m_i^2 edges *from previously uncovered nodes* are deleted in the ith iteration. Consider some $j \in S(i)$. The outdegree of j can be at most m_i just before the ith iteration. Now notice that no edges into an uncovered node can be deleted before the node is covered. Since j is uncovered before the ith iteration, for each edge coming into j from a uncovered node, there is also an edge going out of j to that uncovered node. Thus there can be at most m_i edges coming into j from uncovered nodes, and the total number of edges running from previously uncovered nodes to members in $S(i)$ is at most m_i^2. There may also be edges from previously covered nodes to members of $S(i)$, but we need not consider them, since we are counting (in E_i) only edges from uncovered nodes.

Next, we estimate the number of edges from $S(i)$ to uncovered nodes which are not in $S(i)$. These edges are not deleted by *Greedy*, but they are not counted in the definition of E_i either. It is clear that the outdegree of every node in $S(i)$ must be $\leq m_i - 1$, since the self loops of all such nodes will have been deleted in the ith step. Thus the number of outgoing edges from $S(i)$, after iteration i is $\leq m_i(m_i - 1)$. However, in the first and last iterations, we can tighten this bound slightly. We know that $v_1 \in S(1)$, and so *all* edges entering and leaving v_1 will be deleted after the first iteration. Further, the other nodes in $S(1)$ can have outdegree of at most m_2 at the end of the first iteration. Thus, the number of edges (at the end of the first iteration) from $S(1)$ to uncovered nodes not in $S(1)$ is at most $(m_1 - 1)m_2$. Finally, note that no edges remain at the end of the last iteration, and so the number of edges from $S(d_g)$ to uncovered nodes must be zero.

By the definition of E_i, we conclude that for $2 \leq i < d_g$:

$$E_i \geq E_{i-1} - m_i^2 - m_i(m_i - 1).$$

For the special cases, $i = 1$ and $i = d_g$:

$$E_1 \geq E_o - m_1^2 - (m_1 - 1)m_2,$$

and

$$E_{d_g} \geq E_{d_g - 1} - m_{d_g}^2.$$

$E_{d_g} = 0$ by the definition of d_g. Thus,

$$0 = E_{d_g} \geq - \left(\sum_{i=1}^{d_g} m_i^2 + (m_1 - 1)m_2 + \sum_{i=2}^{d_g-1} m_i(m_i - 1) \right) + E_0.$$

Solving for E_0:

$$E_0 \leq \sum_{i=1}^{d_g} m_i^2 + (m_1 - 1)m_2 + \sum_{i=2}^{d_g-1} m_i(m_i - 1). \tag{2}$$

Now notice that $\sum_{i=1}^{d_g} m_i = N$, and that $m_1 \geq m_2 \geq ... \geq m_{d_g} \geq 1$. We claim that the RHS of (2) attains its maximum with respect to the m_i's subject to the constraints just mentioned, when

$$m_1 = N - d_g + 1, m_2 = m_3 = ...m_{d_g} = 1.$$

This is easily seen to be true by contradiction. Suppose the maximum is achieved so that the highest order m_i which is greater than 1 is not m_1, but say $m_j, j > 1$. Now reduce m_j to 1 and add $m_j - 1$ to m_1 (we can do this because none of the constraints is violated), and the difference in the RHS is seen to be non-negative. This contradicts the assumption.

Substituting the maximum values in the RHS of (2) we have:

$$E_0 = 2M + N \leq (N - d_g + 1)^2 + d_g - 1 + (N - d_g),$$

$$\Rightarrow d_g \leq N + 1 - \sqrt{2M + 1}.$$

Done

The bound of Theorem 1 is met exactly by graphs of the type shown in Figure 3.
